

The Double Chooz Experiment

C. E. Lane (for the Double Chooz collaboration)
Drexel University, Philadelphia, 19104 USA

The Double Chooz experiment returns to the site of the Chooz experiment with a pair of detectors for a differential neutrino flux measurement, providing sensitivity to $\sin^2 2\theta_{13} > 0.03$. Reaching this goal requires significant improvements in systematic uncertainties, based on the experience with previous reactor neutrino experiments.

1. MOTIVATION

Knowledge of the θ_{13} neutrino mixing angle is of great importance for many of the goals of future neutrino research, as described elsewhere[1]. A measurement of θ_{13} using reactor anti-neutrinos would be particularly ‘clean’, with no contamination from other neutrino flavors, no matter effects, and is generally unaffected by other unknown neutrino properties such as the mass hierarchy.

The current limit experimental limit is $\sin^2 2\theta_{13} < 0.17$, depending somewhat on δm^2 , which comes from the Chooz experiment[2]. The Chooz experiment used a single detector, approximately 1 km from a pair of power reactor cores. The Chooz experiment measured a ratio of measured to expected neutrino events[2] of $R = 1.01 \pm 2.8\%(\text{stat}) \pm 2.7\%(\text{syst})$. While the Chooz statistical error is slightly larger, the sensitivity limit of the Chooz experiment came from systematic errors; the experiment was terminated when statistical errors reached the same level as systematic errors, so that little would be gained by continued operation.

2. CHOOZ AND DOUBLE CHOOZ

The Double Chooz experiment has the goal of measuring θ_{13} for values of $\sin^2 2\theta_{13} > 0.03$, or establishing a limit. It is hoped that such a timely measurement will be of use in the design and prioritization of the next steps in experimental neutrino physics. Double Chooz will return to the Chooz site in northern France, where two 4.3 GWth reactors will provide the anti-neutrino flux. The underground laboratory used by the Chooz experiment (≈ 300 m.w.e) has been renovated for the new experiment, saving cost and time. The Chooz experiment had a total systematic uncertainty of 2.7%, of which 1.6% was attributed to absolute detector uncertainty; the lowest of any similar experiment to date.

For Double Chooz, these uncertainties must be reduced by approximately a factor of five. Most of this improvement will be achieved by performing a relative measurement between two detectors placed at ‘near’ (≈ 400 m) and ‘far’ (the existing lab, at 1050 m) sites. One major goal in the construction of the detectors is to make them as identical as possible, however a Bugey[3] experiment attempted to have identical detectors, and found 2% relative error, so it is clear that building identical detectors to within a fraction of a percent is a challenge.

The Double Chooz detectors will be roughly two times larger in target mass than the original Chooz detector, and will be operated longer with full reactor power to improve statistics, yet it is the systematic uncertainty that will be the limitation. It is particularly important to have an accurate appreciation of the sources and size of potential systematics, based on measurements and experience rather than just simulations.

3. EXPERIMENTAL DESIGN

The Double Chooz detectors[4] were designed to improve on the Chooz detector, examining in detail each item in the error budget and incorporating ways to reduce or eliminate uncertainty. Like many previous experiments, Double Chooz will use inverse beta-decay from reactor antineutrinos on target protons, yielding a ‘prompt’ positron

with energy derived from the original neutrino energy, and an epithermal neutron which thermalizes and captures on Gadolinium, giving a ‘delayed’ signal of approximately 8 MeV.

The Double Chooz experiment is being built at the Chooz nuclear reactor power station, in the Ardennes region of northern France, operated by Électricité de France (EDF).

Systematics	Type	Chooz	2 Identical Detectors Low Background
Reactor	Neutrino Flux and Cross-section	1.9%	$\mathcal{O}(0.1\%)$
	Thermal power	0.7%	$\mathcal{O}(0.1\%)$
	E/fission	0.6%	$\mathcal{O}(0.1\%)$
SUM		2.1%	$\mathcal{O}(0.1\%)$

Table I: Comparison of Chooz(absolute) and a two-detector (relative) reactor-based error budgets

A significant amount of the systematic uncertainty in the Chooz result came from ‘reactor-related’ factors, such as the absolute reactor thermal power output (see Tab. I). Using two detectors to make the neutrino measurement relative helps to remove these errors arising from reactor sources. For a single reactor core, these reactor-related effects cancel, even as the reactor power level and fuel composition changes. The Chooz power station has two reactor cores, each of approximately 4.3 GWth at full power. Ideally, the two detectors should be sited so that the distances to the two reactor cores are in the same ratio for both the near and the far detectors. The distance ratio is not exactly identical for Double Chooz (465 m/351 m for the near detector *vs.* 1114.6 m/997.9 m for the far detector), because of practical issues in the siting of the near laboratory, but there still is substantial cancellation of reactor-related systematics to acceptable levels. The ability to cancel reactor-related uncertainties by matching distance ratios only works for one or two reactor cores. More reactor cores gives more overall neutrino flux, but also more systematic error as the reactor cores contribute different (relative) amounts of neutrino flux to the detectors. An additional advantage to using only two reactor cores is that it results in a better ability to measure non-reactor backgrounds during the reactor fueling cycle, by comparing rates during full-power operation to rates during shutdowns. To the extent that background (cosmic-ray or radioactivity) contribute to the systematic uncertainty, the ability to get a clean measurement of the background is very desirable.

Figure 1(a) shows a schematic view of a Double Chooz detector. Like the Chooz detector, there is an inner volume of Gd-loaded scintillator which defines the neutrino target, surrounded by a volume of non-Gd-loaded scintillator for improved capture energy resolution. Surrounding the stainless steel tank is an “Inner Veto” detector, consisting of non-loaded liquid scintillator with 78 Hamamatsu 8-inch R1408 PMTs that were originally used for the IMB experiment[5], then for the Super-K[6] veto, and have been refurbished for Double Chooz. The purpose of the Inner Veto is to tag cosmic-ray muons very efficiently, so that they can be vetoed in analysis. The Inner Veto is surrounded by steel shielding to attenuate radioactivity entering the detector. There is also a cosmic-ray muon tracker system (not shown in the detector figure) that will be installed above the detectors, so that muon-related backgrounds can be more precisely measured.

One simple example of a detector uncertainty is from the mass of protons in the target volume. For the Chooz experiment, this particular uncertainty was a 1% effect on the overall error. Double Chooz will do a relative measurement between two detectors so such uncertainties will largely cancel out to the extent that the detectors can be made identical in construction and operation. The goal for Double Chooz is to achieve a relative uncertainty of 0.6% in ‘detector related’ uncertainties between the near and far detectors. To again take the example of the target mass: one would like the target volumes to be constructed with identical volumes, but realistically the mechanical tolerances, acrylic properties, and other effects indicate that the relative uncertainty may be $\sim 0.6\%$. To reduce this uncertainty, some of the steps Double Chooz will be implementing are: using several techniques for measuring the target scintillator mass, using a scintillator with well-defined chemical composition (to minimize H/C ratio uncertainty) and implementing active thermal measurement and control to ensure that any differences between the two detector targets are known with relative uncertainty $< 0.2\%$.

Figure 1: (a) Schematic view of the Double Chooz detector design. The target volume **T** contains Gd-loaded scintillator, surrounded by a gamma-catcher (**GC**) with non-loaded scintillator for collecting the energy of Gd capture events in the target. Outside the **GC** is a non-scintillating buffer liquid (**B**) to shield the inner volumes and suppress background events near the PMTs. The PMTs (390 Hamamatsu R7081's) that collect light from the inner detector volumes are located inside the buffer **B**, and mounted on a stainless steel tank which provides some shielding and optical isolation. Outside the stainless steel tank is an Inner Veto **IV**, with non-loaded scintillator and PMTs.

(b) Double Chooz $\sin^2 2\theta_{13}$ limit as a function of time after starting operation. For the first (approx.) 1.8 years only the far detector will be running, while the near detector is built, but even as an 'absolute' measurement there will be considerably improvement in sensitivity to θ_{13} over previous experiments. After the start of the near detector, the sensitivity will improve further as a relative measurement can be performed, reducing the systematic uncertainties.

Significant effort is being put toward identifying possible differences between the two detectors, finding means to reduce the differences, and to make measurements that will allow precise compensation. This may seem excessive by the standards of previous reactor neutrino experiments, but when one tries to reduce systematic uncertainties to a fraction of a percent, a level that has not been previously reached by experiments of this type, all sources of possible uncertainty must be examined for their potential effect.

4. ANALYSIS TECHNIQUES

The Chooz experiment had 1.5% systematic uncertainty arising from analysis effects, required a series of seven analysis cuts (positron energy, matching positron and neutron positions, etc.) in order to reduce backgrounds from radioactivity, for an overall neutrino event efficiency of $\approx 70\%$. The Double Chooz detector has been designed to eliminate the problems with radioactivity seen in Chooz, by adding a buffer volume, and selecting detector components for low activity. The Double Chooz detector is designed such that only a minimum number of analysis cuts are needed (see Tab. II). The result is fewer analysis cuts: three (or two, with low background) for Double Chooz data, minimizing systematics for each cut, with an overall contribution to systematic uncertainty of $\sim 0.3\%$.

To see the development between Chooz and Double Chooz, a "Positron Energy" cut of 1.3 MeV was needed in Chooz to reduce low-energy background, but introduced systematics from the knowledge of the threshold, from inhomogeneous energy response in the detector, and from scintillator variation with time, all of which contributed to the 'Positron Energy' uncertainty listed above. In Double Chooz the non-scintillating buffer and other background reduction measures will greatly decrease the rate of low-energy backgrounds, allowing Double Chooz to use just a hardware energy threshold set well below 1 MeV, and eliminate the "Positron Energy" cut and its systematic uncertainty.

cut	Chooz		Double Chooz	
	rel. err(%)	rel. err(%)	comment	
Positron Energy*	0.8	0	not used	
Positron-Geode distance	0.1	0	not used	
Neutron capture on Gd	1.0	0.2	Cf calibration	
Capture energy containment	0.4	0.2	Energy calibration	
Neutron-Geode distance	0.1	0	not used	
Neutron delay	0.4	0.1	–	
Positron-Neutron distance	0.3	0–0.2	0 if not used	
Neutron multiplicity*	0.5	0	not used	
Combined	1.5	0.2–0.3

Table II: Comparison of analysis systematic uncertainties for Chooz and Double Chooz. An improved detector design reduces backgrounds, allowing the elimination of many cuts.

5. PROGRESS, TIMESCALE, CONCLUSIONS

At the time of this writing (Sep. 2008) the Double Chooz far detector construction has been underway for a few months. The installation of the Inner Veto PMTs is expected near the beginning of 2009, followed by the insertion of the inner stainless steel tank, inner PMTs, acrylic vessels, etc., with the ‘first neutrino event’ expected by Summer 2009. Figure 1(b) shows the anticipated sensitivity of Double Chooz to θ_{13} as a function of time from when the far detector starts operation.

While later experiments will no doubt improve the statistics of a θ_{13} search, pushing further downward in θ_{13} is primarily a matter of reducing the systematics. The largest improvement in systematics comes from moving from an absolute (Chooz) to a relative measurement (Double Chooz). Operating additional detectors at similar distances will allow comparisons that can improve how systematics are quantified, but it is much less clear that a simple ‘scale up’ would significantly improve the measurement of θ_{13} unless the underlying sources of systematic uncertainties are addressed.
